# TinyStress: Lightweight TinyML for Real-time Stress Detection on Wearable Devices

***Abstract*—Wearable device-enabled real-time stress detection offers valuable insights for mental health monitoring and well-being assessment. Recent studies have increasingly adopted deep neural network (NN) to this setting because of its strong representation learning capability. However, they typically requires large NNs to achieve reliable outcomes, which is infeasible on wearable devices due to computational, memory, and power limitations. This paper introduces TinyStress, a TinyML-based stress classification model tailored for edge and wearable deployment. Our approach uses a compact CNN architecture based on depthwise separable convolutions to reduce MACs and memory footprint, enabling it well-suited for always-on inference under tight energy budgets. We prototyped TinyStress on an experimental testbed using an Arduino Nano 33 BLE Sense as to measure energy consumption, memory footprint, and inference latency. Extensive results on WESAD dataset demonstrated that our approach achieves a 3× reduction in computational complexity compared with a standard CNN-based model, while incurring only a 3% accuracy decrease. On hardware, it also reduce flash footprint, inference time and energy usage, respectively, by up to 1.5×, 4×, and 3×, offering a cost-effective, real-time, and energy-efficient solution for continuous stress monitoring.**

***Index Terms*—Stress Detection, TinyML, Depthwise Separable Convolution.**

## I. Introduction

**Motivation.** Stress has become a major health concern with serious consequences for both physical and mental well-being. Prolonged stress exposure is associated with cardiovascular conditions, anxiety and depression, weakened immune responses, and lower productivity, underscoring the importance of effective real-time monitoring and management [1], [2]. Conventional stress assessment has largely depended on subjective instruments, including self-report questionnaires and clinician-administered evaluations. Although these approaches can capture aspects of psychological state, they are vulnerable to reporting and observer biases, occur only intermittently, and are poorly suited for continuous, real-time monitoring [3]. Consequently, there is growing demand for objective, continuous, and noninvasive stress sensing, accelerating the development of next-generation wearable technologies.

Among wearable modalities, photoplethysmography (PPG) is widely adopted due to its easy integration into consumer devices, noninvasive sensing, low cost, and comfort for long-term use [4]. PPG measures peripheral blood volume changes, providing signals that reflect autonomic nervous system activity relevant to stress [5]. However, PPG is highly susceptible to motion artifacts, ambient light interference, and inter-subject physiological variability, requiring robust signal processing [6]. Conventional feature-engineering approaches [7] often employ numerous handcrafted descriptors or frequency-domain transformations. It not only attains limited accuracy (i.e., ∼74%) but also incurs substantial resource overhead (i.e., 1.2 MB memory), which can impede real-time deployment on resource-constrained embedded devices that are limited to 1 MB of flash storage. On the other hand, recent studies have investigated the integration of deep learning (DL) into wearable devices to enhance the performance. For instance, [8] introduced a LSTM-based approach, and [9], [10] utilized standard CNN to enhance the performance, achieving ∼85% in accuracy.

**Existing Limitation.** Despite this advantage, several limitations still hinder the practical deployment of DL-based wearable sensing systems. In particular, almost healthcare applications require reliable performance under real-world conditions, which often motivates the use of large and computationally intensive models. For example, [8] using LSTM-based approach require 10.2 MB of storage, while [9], [10] with 1D-CNN also demand 0.6 MB. Such models are struggle to run on wearable devices due to strict constraints on energy consumption, memory footprint, and battery life. This motivates the following research question: *"How can we design an effective DL-based model that can operate directly on resource-constrained wearable devices?"*

**Key Contributions.** We response this question by proposing TinyStress, a TinyML-based model for stress detection from physiological signals that preserves high accuracy while enabling on-device deployment. Our design adopts depthwise separable convolutions (DSConv) as the backbone of the network. The core idea of DSConv is to factorize a standard convolution into two stages: i) a "*depthwise*" convolution that performs spatial filtering independently on each input channel, followed by a "*pointwise*" convolution that mixes information across channels. This decomposition substantially reduces the number of parameters and multiply–accumulate operations compared to conventional convolutions, thereby lowering model complexity and inference latency.

***Summary of the main contributions***

- We propose TinyStress, a lightweight TinyML stress-detection model that utilizes DSConv as its backbone to reduce memory footprint and latency overhead while maintaining competitive accuracy. This design enables continuous, energy-efficient stress tracking for always-on wearable operation.
- We prototype TinyStress on an experimental testbed consisting of Arduino Nano 33 BLE Sense as resource-

limited wearable device, to measure energy consumption, memory footprint, and inference latency. Experimental results indicate that our approach achieves a 3× reduction in computational complexity compared to standard CNN-based model, while incurring only a 3% accuracy decrease. It also reduces flash footprint, inference time, and energy usage, respectively, by up to 1.5×, 4×, and 3×, making it well-suited for efficient deployment on embedded and wearable platforms.

**Paper organization.** Section II reviews related work, and Section III presents the `TinyStress` framework, while Section IV evaluates its performance. Finally, Section V concludes the paper.

## II. Related Work

**PPG-based Stress Detection.** PPG has been widely studied for stress detection because it captures stress-related hemodynamic signatures such as heart rate variability and pulse amplitude. For example, prior work [11] reported that PPG-derived features, combined with additional physiological signals, achieved roughly 90% accuracy for stress recognition in real-world driving tasks. While these studies [7]–[10] established PPG's feasibility, their reliance on computationally heavy feature extraction limits real-time deployment on wearable devices. Notably, recent work have increasingly combined PPG with additional physiological signals such as electrodermal activity or skin temperature to further improve performance. For instance, [12] integrated PPG and EDA signals to achieve stress classification accuracies exceeding 95% under controlled lab conditions. However, the computational burden grows with each added sensor modality, creating obstacles for continuous real-time use on power-constrained devices.

**Deep Learning in Stress Detection.** Deep learning models have recently simplified feature extraction by learning discriminative patterns directly from raw signals. For instance, [13] proposed an LSTM-based real-times tress classification system that processes raw PPG waveform low-power platforms, maintaining around 90% accuracy. However, many deep architectures remain compute-intensive, and minimizing preprocessing can degrade performance when raw signals are noisy. Therefore, TinyML approaches have been proposed to balance accuracy and efficiency. For example, [14] showed that wavelet-based features combined with a pruned CNN can maintain strong accuracy with model sizes under 2 MB. Similarly, [15] used an autoencoder for feature extraction with an edge-oriented SVM classifier, achieving nearly 95% accuracy. Nevertheless, many of these methods depend on complex hand-crafted features or transform-based preprocessing, which can hinder generalization and complicate deployment. To address these limitations, we propose a lightweight TinyML approach for stress classification that maintains high accuracy while reducing energy consumption and inference latency, enabling real-time on-device deployment on wearable platforms.

## III. Method

### A. Overview

We propose a lightweight end-to-end architecture for classifying stress-related physiological patterns from raw PPG signals. Given a fixed-length PPG window $\mathbf{x} \in \mathbb{R}^T$ with an input length $T$, the model predicts a categorical label $y \in \{1, \ldots, C\}$ by extracting hierarchical temporal representations using a depthwise separable 1D convolutional backbone, followed by global aggregation and a compact classifier, as shown in Fig. 1. Our design tends to have a low compute and memory footprint while maintaining competitive accuracy, making it suitable for deployment on resource-constrained devices.

### B. `TinyStress` Architecture

**Pre-processing.** Each raw PPG window $\mathbf{x} \in \mathbb{R}^T$ is reshaped into a single-channel sequence $\mathbf{X} \in \mathbb{R}^{T\times 1}$. We standardize the input using statistics computed on the training set:

$$\tilde{\mathbf{X}} = \frac{\mathbf{X} - \mu}{\sigma + \epsilon}, \tag{1}$$

where $\mu$ and $\sigma$ are the training-set mean and standard deviation, respectively, and $\epsilon$ is a small constant for numerical stability. This normalization reduces inter-subject and inter-session scale variations and stabilizes training.

**DSConv Block.** Let $\mathbf{H}^{(0)} = \tilde{\mathbf{X}}$ denote the normalized input. The backbone consists of $B$ convolutional blocks. The $b$-th block transforms $\mathbf{H}^{(b-1)} \in \mathbb{R}^{T_{b-1}\times F_{b-1}}$ to $\mathbf{H}^{(b)} \in \mathbb{R}^{T_b\times F_b}$ using a depthwise separable 1D convolution (DSConv), batch normalization, a pointwise nonlinearity, and optional max pooling.

*a) Depthwise separable convolution:* DSConv factorizes a standard 1D convolution into a depthwise operation (channel-wise temporal filtering) and a pointwise operation (channel mixing). Specifically, the block first applies a depthwise temporal convolution with kernel size $k_b$ independently on each input channel, producing an intermediate representation:

$$\mathbf{U}^{(b)} = \mathrm{DWConv1D}\Big(\mathbf{H}^{(b-1)}; k_b\Big), \tag{2}$$

and then applies a $1\times 1$ pointwise convolution to mix channels and obtain $F_b$ output channels:

$$\mathbf{Z}^{(b)} = \mathrm{PWConv1D}\Big(\mathbf{U}^{(b)}; F_b\Big). \tag{3}$$

Compared to a standard convolution with parameter cost $k_b F_{b-1} F_b$, DSConv reduces parameters to $k_b F_{b-1} + F_{b-1} F_b$, which yields substantial savings when $k_b > 1$ and $F_b$ is moderate.

*b) Batch normalization and activation:* To stabilize intermediate feature distributions, we apply batch normalization to $\mathbf{Z}^{(b)}$:

$$\bar{\mathbf{Z}}^{(b)} = \mathrm{BN}\Big(\mathbf{Z}^{(b)}\Big), \tag{4}$$

followed by a pointwise nonlinearity (ReLU in our implementation):

$$\mathbf{A}^{(b)} = \phi\Big(\bar{\mathbf{Z}}^{(b)}\Big). \tag{5}$$

Fig. 1. Diagram of `TinyStress`.

*c) Temporal downsampling via max pooling:* To progressively increase the effective receptive field and reduce computational cost, we apply temporal max pooling after configurable block intervals. When pooling is enabled at block $b$, we obtain:

$$\mathbf{H}^{(b)} = \mathrm{MaxPool1D}\left(\mathbf{A}^{(b)}; s\right), \tag{6}$$

where $s$ is the pooling size (and stride) along the temporal dimension. When pooling is disabled at block $b$, we set $\mathbf{H}^{(b)} = \mathbf{A}^{(b)}$. This design allows flexible control over the temporal resolution schedule while keeping the model lightweight.

*d) Classifier Head:* After the final convolutional block,we implement a fully connected layer to form a compact latent representation:

$$\mathbf{r} = \phi(\mathbf{W}_1\tilde{\mathbf{g}} + \mathbf{b}_1), \tag{7}$$

and a final linear projection with softmax to produce class probabilities:

$$\mathbf{o} = \mathbf{W}_2\mathbf{r} + \mathbf{b}_2,$$

$$\hat{\mathbf{y}} = \mathrm{Softmax}(\mathbf{o}). \tag{8}$$

### C. Discussion

The proposed architecture combines (i) depthwise separable temporal filtering to reduce parameter and compute complexity, (ii) batch normalization and nonlinear activations to improve optimization stability, (iii) max pooling to control temporal resolution and enlarge receptive fields, and (iv) the lightweight classifier head for compact decision making. This design provides an effective accuracy–efficiency trade-off for raw PPG-based stress classification under deployment constraints.

## IV. Experiment Evaluation

### A. Experimental Settings

**Datasets.** We consider the WESAD dataset [12], which contains multi-modal physiological signals collected from 15 subjects under different emotional and physical conditions collected from both awristworn Empatica E4 device and a chest-worn RespiBAN sensor. Although WESAD dataset includes various physiological signals, we use the PPG signal was selected for analysis due to its prevalence in wearable technology and non-invasive nature. Each subject's data covers two relevant states, including 1) Baseline (Calm) State and 2) Stress State. Our experiments used the PPG signals sampled at 64 Hz, focusing exclusively on these two states for binary classification (stress vs. no stress).

**Implementation Details.**

*a) Segmentation Technique:* Following the filtering stage, the clean PPG signal was segmented using a sliding window technique to prepare fixed-length input segments suitable for machine learning models. This approach divides the continuous PPG signal into overlapping windows, ensuring temporal consistency while maximizing the use of available data. The segmentation was performed using a sliding window approach with a window size of 512 samples, corresponding to 8 seconds at a sampling rate of 64 Hz. Each window overlapped the previous by 25% (128 samples), with a step size of 384 samples to advance the window. This overlapping strategy ensures that no significant transitional information between windows is lost, crucial for preserving the continuity of physiological signals and enhancing model performance.

*b) Filtering Technique:* ...

*c) Simulation Hyperparameter:* The proposed approach and baselines are implemented in PyTorch and trained on a T4-GPU (Google Colab) for 50 epochs using the Adam optimizer, with a batch size of 128, a learning rate of 0.001, and a momentum of 0.9. We use 4 CNN blocks, and the kernel sizes are 9, 7, 5, and 3, respectively.

**Baselines and Evaluation Metrics.** In this work, we adopt a standard 1D CNN-based model as a baseline to establish a strong yet lightweight reference point. To quantify the performance-complexity trade-off, we report classification effectiveness using accuracy, macro-F1 score and confusion matrix, and characterize model complexity using the total number of trainable parameters. In addition, we deploy both models on embedded hardware to assess practical feasibility

TABLE I
STRESS DETECTION PERFORMANCE COMPARISON BETWEEN DIFFERENT SCHEMES ON SEWAD DATASET.

| Methods | Accuracy (%) ↑ | F1-score ↑ | Confusion Matrix | Model Complexity (Kb) ↓ |
|---|---|---|---|---|
| Standard CNN Model | 89.11 | 87.84 | 2027 299<br>65 950 | 68.95 |
| DSConv Model | 85.75 | 81.52 | 2232 94<br>382 633 | 29.54 |
| Δ | 3.36 | 6.32 | NA | 39.41 |

Fig. 2. Experimental setup for performance evaluation to evaluate the on-hardware resource consumption.

under real device constraints, including flash storage usage and runtime memory footprint. In addition, we report CPU active time (%), defined as the fraction of the measurement window during which the microcontroller is active (i.e., not in sleep mode). We further measure on-device inference time per sample. Finally, we use an energy proxy, which approximates the total CPU work per second by aggregating computation, buffer preparation, and communication handling.

**On-hardware Implementation.** As shown in Fig. 2, we set up a scenario to evaluate resource consumption. In particular, we use a Arduino Sense 33 BLE as the resource constrained wearable device to evaluate storage requirements and runtime memory footprint. Furthermore, we integrate an OLED display and the MAX30105 sensor to support real-time operation.

### *B. Experimental Results*

*1) Accuracy and Model Complexity in Offline Simulation:*

**Accuracy and Macro-F1 Score.** The results in Tab. I reveal a consistent accuracy-efficiency trade-off between the standard 1D CNN baseline and the proposed DSConv variant on the SEWAD dataset. The standard CNN achieves the highest predictive performance, reaching 89.11% accuracy and 87.84 macro-F1, whereas DSConv attains 85.75% accuracy and 81.52 macro-F1. This indicates that replacing full convolutions with DSConv reduces representational capacity to some extent in our current configuration, leading to a measurable drop in classification quality (3.36% in accuracy and 6.32 points in F1).

**Confusion Matrix.** A closer inspection of the confusion matrices suggests that the performance gap is primarily driven by increased misclassification of positive (stress) samples under DSConv. Specifically, DSConv produces more false negatives (382 vs. 65 for the baseline) and fewer true positives (633 vs. 950), implying reduced sensitivity to stress events. In contrast, DSConv yields fewer false positives (94 vs. 299) and more true negatives (2232 vs. 2027), which reflects a more conservative decision boundary. This asymmetric error profile is important for stress monitoring: depending on the target application, false negatives may be costlier than false positives (e.g., missed stress episodes in continuous monitoring), and thus model selection should be guided by the operational preference for sensitivity versus specificity.

TABLE II
ON-DEVICE COMPARISON ON ARDUINO NANO 33 BLE (TFLITE MICRO).

| Metric | DSConv | Standard 1D CNN |
|---|---|---|
| Program storage (bytes) | 410,392 (41%) | 599,800 (61%) |
| Max program storage (bytes) | 983,040 | 983,040 |
| Global variables (bytes) | 154,920 (59%) | 154,928 (59%) |
| Free dynamic memory (bytes) | 107,224 | 107,216 |
| Max dynamic memory (bytes) | 262,144 | 262,144 |
| CPU active (%) | 23.8 | 35.6 |
| Inference time (ms) | 50.678 | 192.957 |
| Energy proxy (ms/s) | 139.965 | 431.781 |

**Model Complexity.** Despite the drop in offline performance, DSConv offers a substantial reduction in model complexity, decreasing the model size from 68.95 KB to 29.54 KB. This corresponds to a 39.41 KB reduction, or approximately 57% relative compression. Such savings directly translate to lower flash usage and typically lower compute requirements, which are critical constraints for wearable deployment. In scenarios where memory budget or energy consumption is the primary bottleneck, DSConv provides a favorable operating point that enables on-device inference with reduced storage demands, potentially allowing additional signal processing, robustness modules, or multi-task extensions within the same hardware envelope.

**Discussion.** Overall, Tab. I indicates that DSConv is an effective efficiency-oriented alternative to the standard CNN, but its current instantiation trades away sensitivity to stress. This motivates two practical follow-up directions: first, tuning DSConv capacity (e.g., modestly increasing channel widths in later blocks or adjusting kernel schedules) to recover F1 while maintaining a small footprint; and second, optimizing decision thresholds or incorporating cost-sensitive training to better control the false-negative rate in deployment settings.

*2) Resource Consumption on Hardware:*

**Flash Footprint.** The on-device results in Tab. II highlight

a clear efficiency advantage of the proposed DSConv backbone over the standard 1D CNN baseline under identical deployment constraints. First, DSConv substantially reduces flash footprint, requiring 410.392 bytes (41% of available program storage) compared to 599.800 bytes (61%) for the baseline. This $\sim$31.6% reduction is practically important for microcontroller deployments where program memory is often the primary bottleneck, and it enables additional headroom for sensor I/O, signal processing, and application logic.

**Memory Usage.** The two models exhibit nearly identical dynamic memory usage (global variables ($\approx$ 155) KB, leaving ($\approx$ 107) KB for local allocations), indicating that RAM consumption is dominated by shared runtime components (e.g., tensor arena, buffering, and system code) rather than model parameters alone. Consequently, while DSConv reduces parameter count and flash storage, it does not necessarily reduce peak RAM in the current implementation. This suggests that further RAM savings would likely require reducing intermediate activation sizes (e.g., fewer channels, more aggressive pooling) or employing quantized inference with smaller tensor buffers.

**CPU Active.** DSConv yields a meaningful reduction in compute-related cost at runtime. The CPU active fraction drops from 35.6% to 23.8%, and the measured inference workload decreases from 192.957 to 50.678 ms per second, corresponding to a $\sim$3.8$\times$ reduction in time spent inside the inference kernel. Consistently, the overall energy proxy (which aggregates inference, input filling, and serial processing time) decreases from 431.781 to 139.965 ms per second ($\sim$3.1$\times$). These results indicate that DSConv improves the end-to-end efficiency not only at the model level but also at the system level, reducing the fraction of time the MCU remains active and therefore improving energy efficiency in streaming operation.

**Inference Time.** The reduction in inference cost does not translate to proportional RAM savings, and the absolute inference burden remains non-trivial under float32 TFLite Micro execution. This behavior is consistent with microcontroller inference pipelines where runtime buffers and operator implementations can dominate resource usage. In future iterations, enabling integer quantization (e.g., full int8) and optimized kernels would be expected to further reduce latency and energy, potentially unlocking higher inference rates or lower duty cycles for continuous sensing scenarios.

## V. Conclusion

This paper presented `TinyStress` , a lightweight TinyML stress-detection model designed for continuous, on-device inference on resource-constrained wearables. `TinyStress` adopts a depthwise separable 1D CNN backbone to reduce computational and storage demands while maintaining competitive classification performance. Experiments on WESAD demonstrate that `TinyStress` achieves a favorable accuracy–efficiency trade-off, delivering approximately a 3× reduction in computational complexity with only a modest drop in accuracy relative to a standard 1D CNN baseline. On an Arduino Nano 33 BLE Sense (TFLite Micro), `TinyStress` further translates these algorithmic savings into system-level benefits, reducing flash footprint, inference workload, and the overall energy proxy substantially compared with the baseline, enabling more practical always-on operation under tight energy budgets.
